Operational Amplifiers B.Sc. Physics (III) Presented by Dr.R.Mary Mathelane M. Phil Physics Associate Professor

## **Operational Amplifiers**

#### Introduction: Ideal Operational Amplifier

Operational amplifier (Op-amp) is made of many transistors, diodes, resistors and capacitors in integrated circuit technology.

Ideal op-amp is characterized by:

- Infinite input impedance
- Infinite gain for differential input
- Zero output impedance

Infinite frequency bandwidth

Figure 14.1 Circuit symbol for the op amp.

# **Circuit Symbol and Pin Identification**

- 2 Inverting Input
- 3 Non-Inverting Input
- 6 Output
- 7 + Voltage Supply
  V<sub>CC</sub>
- 4 Voltage Supply
  V<sub>EE</sub>
- 1 and 5 -- Offset Null

- There are two inputs
  - inverting and non-inverting
- And one output
- Also power connections (note no explicit ground)

Winter 2012

### The ideal op-amp

- Infinite voltage gain
  - a voltage difference at the two inputs is magnified infinitely
  - in truth, something like 200,000
  - means difference between + terminal and terminal is amplified by 200,000!
- Infinite input impedance
  - no current flows into inputs
  - in truth, about  $10^{12} \Omega$  for FET input op-amps
- Zero output impedance
  - rock-solid independent of load
  - roughly true up to current maximum (usually 5–25 mA)
- Infinitely fast (infinite bandwidth)
  - in truth, limited to few MHz range
  - slew rate limited to 0.5–20 V/ $\mu$ s

#### **Inverting Amplifier**

Op-amp are almost always used with a negative feedback: Part of the output signal is returned to the input with negative sign

Feedback reduces the gain of op-amp

•Since op-amp has large gain even small input produces large output, thus for the limited output voltage (lest than  $V_{CC}$ ) the input voltage  $v_x$  must be very small.

•Practically we set  $R_{X}$  to zero when analyzing the op-amp

Figure 14.4 The inverting amplifier.

with  $v_x = 0$   $i_1 = v_{in}/R_1$ 

$$i_2 = i_1$$
 and

 $v_o = -i_2 R_2 = -v_{in} R_2/R_1$ so  $A_v = v_o/v_{in} = -R_2/R_1$ 

## **Op-amp without feedback**

• The internal op-amp formula is:

 $V_{out} = gain \times (V_+ - V_-)$ 

- So if  $V_{+}$  is greater than  $V_{-}$ , the output goes positive
- If  $V_{-}$  is greater than  $V_{+}$ , the output goes negative

• A gain of 200,000 makes this device (as illustrated here) practically useless

## Infinite Gain in negative feedback

- Infinite gain would be useless except in the selfregulated negative feedback regime
  - negative feedback seems bad, and positive good—but in electronics positive feedback means runaway or oscillation, and negative feedback leads to stability
- Imagine hooking the output to the inverting terminal:
- If the output is less than  $V_{in}$ , it shoots positive
- If the output is greater than  $V_{in}$ , it shoots negative
  - result is that output quickly forces itself to be exactly  $V_{in}$

negative feedback loop

Winter 2012

#### Even under load

- Even if we load the output (which as pictured wants to drag the output to ground)...
  - the op-amp will do everything it can within its current limitations to drive the output until the inverting input reaches  $V_{in}$
  - negative feedback makes it self-correcting
  - in this case, the op-amp drives (or pulls, if  $V_{in}$  is negative) a current through the load until the output equals  $V_{in}$
  - so what we have here is a buffer: can apply  $V_{in}$  to a load without burdening the source of  $V_{in}$  with *any* current!

Important note: op-amp output terminal sources/sinks current at will: not like inputs that have no current flow

#### Positive feedback pathology

- In the configuration below, if the + input is even a smidge higher than  $V_{in}$ , the output goes way positive
- This makes the + terminal even more positive than V<sub>in</sub>, making the situation worse
- This system will immediately "rail" at the supply voltage
  - could rail either direction, depending on initial offset

positive feedback: BAD

## **Op-Amp "Golden Rules"**

- When an op-amp is configured in any negativefeedback arrangement, it will obey the following two rules:
  - The inputs to the op-amp draw or source no current (true whether negative feedback or not)
  - The op-amp output will do whatever it can (within its limitations) to make the voltage difference between the two inputs zero

## Inverting amplifier example

- Applying the rules: terminal at "virtual ground"
   so current through R<sub>1</sub> is I<sub>f</sub> = V<sub>in</sub>/R<sub>1</sub>
- Current does not flow into op-amp (one of our rules)
  - so the current through  $R_1$  must go through  $R_2$
  - voltage drop across  $R_2$  is then  $I_f R_2 = V_{in} \times (R_2/R_1)$
- So  $V_{\text{out}} = 0 V_{\text{in}} \times (R_2/R_1) = -V_{\text{in}} \times (R_2/R_1)$
- Thus we amplify  $V_{in}$  by factor  $-R_2/R_1$ 
  - negative sign earns title "inverting" amplifier
- Current is *drawn into* op-amp output terminal

Winter 2012

## **Non-inverting Amplifier**

- Now neg. terminal held at V<sub>in</sub>
  - so current through  $R_1$  is  $I_f = V_{in}/R_1$  (to left, into ground)
- This current cannot come from op-amp input
  - so comes through  $R_2$  (delivered from op-amp output)
  - voltage drop across  $R_2$  is  $I_f R_2 = V_{in} \times (R_2/R_1)$
  - so that output is higher than neg. input terminal by  $V_{in} \times (R_2/R_1)$
  - $V_{\text{out}} = V_{\text{in}} + V_{\text{in}} \times (R_2/R_1) = V_{\text{in}} \times (1 + R_2/R_1)$
  - thus gain is  $(1 + R_2/R_1)$ , and is positive
- Current is sourced from op-amp output in this example

## **Summing Amplifier**

- Much like the inverting amplifier, but with two input voltages
  - inverting input still held at virtual ground
  - $I_1$  and  $I_2$  are added together to run through  $R_f$
  - so we get the (inverted) sum:  $V_{out} = -R_f \times (V_1/R_1 + V_2/R_2)$ 
    - if  $R_2 = R_1$ , we get a sum proportional to  $(V_1 + V_2)$
- Can have any number of summing inputs
  - we'll make our D/A converter this way

#### Differencing Amplifier $R_1$ $V \rightarrow V_{out}$ $R_1$ $V \rightarrow V_{out}$ $R_1$ $R_2$ $R_2$

• The non-inverting input is a simple voltage divider:

 $- V_{\rm node} = V^+ R_2 / (R_1 + R_2)$ 

- So  $I_{\rm f} = (V V_{\rm node})/R_1$ 
  - $V_{\text{out}} = V_{\text{node}} I_{\text{f}}R_2 = V^+(1 + R_2/R_1)(R_2/(R_1 + R_2)) V^-(R_2/R_1)$
  - so  $V_{\text{out}} = (R_2/R_1)(V^+ V^-)$
  - therefore we difference  $V^{+}$  and  $V^{-}$

- For a capacitor, Q = CV, so  $I_{cap} = dQ/dt = C \cdot dV/dt$ - Thus  $V_{out} = -I_{cap}R = -RC \cdot dV/dt$
- So we have a differentiator, or high-pass filter
  - if signal is  $V_0 \sin \omega t$ ,  $V_{out} = -V_0 RC \omega \cos \omega t$
  - the  $\omega$ -dependence means higher frequencies amplified more

•  $I_f = V_{in}/R$ , so  $C \cdot dV_{cap}/dt = V_{in}/R$ 

- and since left side of capacitor is at virtual ground:

$$-dV_{out}/dt = V_{in}/RC$$
  
- so  $V_{out} = -\frac{1}{RC} \int V_{in} dt$ 

and therefore we have an integrator (low pass)

#### **RTD Readout Scheme**

## Notes on RTD readout

- RTD has resistance R =  $1000 + 3.85 \times T(^{\circ}C)$
- Goal: put 1.00 mA across RTD and present output voltage proportional to temperature:  $V_{out} = V_0 + \alpha T$
- First stage:
  - put precision 10.00 V reference across precision  $10k\Omega$  resistor to make 1.00 mA, sending across RTD
  - − output is −1 V at 0°C; −1.385 V at 100°C
- Second stage:
  - resistor network produces 0.25 mA of source through R9
  - R6 slurps 0.25 mA when stage 1 output is -1 V
    - so no current through feedback  $\rightarrow$  output is zero volts
  - At 100°C, R6 slurps 0.346 mA, leaving net 0.096 that must come through feedback
  - If R7 + R8 = 10389 ohms, output is 1.0 V at 100°C
- Tuning resistors R11, R7 allows control over offset and gain, respectively: this config set up for  $V_{out} = 0.01T$

## **Hiding Distortion**

- Consider the "push-pull" transistor arrangement to the right
  - an npn transistor (top) and a pnp (bot)
  - wimpy input can drive big load (speaker?)
  - base-emitter voltage differs by 0.6V in each transistor (emitter has arrow)
  - input has to be higher than ~0.6 V for the npn to become active
  - input has to be lower than -0.6 V for the pnp to be active
- There is a no-man's land in between where neither transistor conducts, so one would get "crossover distortion"
  - output is zero while input signal is between -0.6 and 0.6 V

#### UCSD: Physics 121; 2012

## Stick it in the feedback loop!

- By sticking the push-pull into an op-amp's feedback loop, we guarantee that the output faithfully follows the input!
  - after all, the golden rule demands that + input = input
- Op-amp jerks up to 0.6 and down to -0.6 at the crossover
  - it's almost magic: it figures out the vagaries/nonlinearities of the thing in the loop
- Now get advantages of push-pull drive capability, without the mess Winter 2012 27

## Dogs in the Feedback

- The op-amp is obligated to contrive the inverse dog so that the ultimate output may be as tidy as the input.
- Lesson: you can hide nasty nonlinearities in the feedback loop and the op-amp will "do the right thing"

We owe thanks to Hayes & Horowitz, p. 173 of the student manual companion to the *Art of Electronics* for this priceless metaphor.
